# ECON526: Quantitative Economics with Data Science Applications

Foundations of Numerical Linear Algebra

Jesse Perla

### Table of contents i

Basic Linear Algebra

Solving Linear Systems of Equations

Eigenvalues and Eigenvectors

Least Squares and the Normal Equations

#### **Motivation and Materials**

- · Data science, econometrics, and macroeconomics are built on linear algebra.
- Numerical linear algebra has all sorts of pitfalls, which become more critical as we scale up to larger problems.
- · Speed differences in choosing better algorithms can be orders of magnitude.
- Crucial to know what goes on under-the-hood in Stata/R/python packages for applied work, even if you don't implement it yourself.
- · Material here is related to
  - · QuantEcon Python
  - · QuantEcon Data Science
  - · A First Course in Quantitative Economics with Python

#### **Packages**

This section uses the following packages:

```
import numpy as np
import matplotlib.pyplot as plt
import scipy
from numpy.linalg import cond, matrix_rank, norm
from scipy.linalg import inv, solve, det, eig, lu, eigvals
from scipy.linalg import solve_triangular, eigvalsh, cholesky
```

Δ

## **Basic Computational Complexity**

#### Definition (Big-O Notation)

For a function f(N) and a positive constant C, we say f(N) is O(g(N)), if there exist positive constants C and  $N_0$  such that:

$$0 \leq f(N) \leq C \cdot g(N) \quad \text{for all } N \geq N_0$$

- $\cdot$  Often crucial to know how problems scale asymptotically (as  $N o \infty$ )
- $\cdot$  Caution:  $f_1(N) = N^3 + N$  is  $O(N^3)$  and  $f_2(N) = 1000N^2 + 3N$  is  $O(N^2)$ 
  - Asymptotically choose  $f_2(N)$  algorithm, but choose  $f_1(N)$  for small N
- · Simple examples:
  - $\cdot \ x \cdot y = \sum_{n=1}^N x_n y_n$  is O(N) since it requires N multiplications and additions
  - $\cdot \ Ax$  for  $A \in \mathbb{R}^{N \times N}, x \in \mathbb{R}^N$  is  $O(N^2)$  since it requires N dot products, each O(N)

#### **Numerical Precision**

Computers have finite precision. 64-bit typical, but 32-bit on GPUs

#### Definition (Machine Epsilon)

```
For a given datatype, \epsilon is defined as \epsilon = \min_{\delta > 0} \left\{ \delta : 1 + \delta > 1 \right\}
```

```
print(f"machine epsilon for float64 = {np.finfo(float).eps}")
print(f"1 + eps/2 == 1? {1.0 + 1.1e-16 == 1.0}")
print(f"machine epsilon for float32 = {np.finfo(np.float32).eps}")
```

```
machine epsilon for float64 = 2.220446049250313e-16
1 + eps/2 == 1? True
machine epsilon for float32 = 1.1920928955078125e-07
```

Basic Linear Algebra

#### Norms

- $\cdot$  Common measure of "size" is the Euclidean norm, or  $L^2$  norm for  $x \in \mathbb{R}^2$
- $\cdot$  Complexity is O(N): requires squaring N times then N additions to sum. Not nested

$$||x||_2 = \sqrt{\sum_{n=1}^N x_n^2}$$
 x = np.array([1, 2, 3]) # Calculating different ways (in order of preference)

- print(np.sqrt(sum(xval\*\*2 for xval in x))) # manual with comprehensions
- print(np.sqrt(np.sum(np.square(x)))) # broadcasts
- print(norm(x)) # built-in to numpy norm(x, ord=2) alternatively
- print(f"||x||\_2^2 = {norm(x)\*\*2} = {x.T @ x} = {np.dot(x, x)}")
- 3.7416573867739413
- 3.7416573867739413
- 3.7416573867739413 $||x||_2^2 = 14.0 = 14 = 14$

## Solving Systems of Equations

```
Then since A^{-1}A = I, and Ix = x, we have x = A^{-1}b. Careful since matrix algebra is not commutative!

A = np.array([[0, 2], [3, 4]]) # or ((0, 2), (3, 4))

b = np.array([2,1]) # Column vector

x = solve(A, b) # Solve Ax = b for x

x = array([-1., 1.])
```

· Solving Ax = b for x is equivalent  $A^{-1}Ax = A^{-1}b$ 

# Using the Inverse Directly

array([-1., 1.])

- · Can replace the **solve** with a calculation of an inverse
- But it can be slower or less accurate than solving the system directly

```
A_inv = inv(A)
A_inv @ b # i.e, A^{-1} * b
```

С

#### **Linear Combinations**

We can think of solving a system as finding the linear combination of columns of A that equal b

```
b_star = x[0] * A[:, 0] + x[1] * A[:, 1] # using x solution
print(f"b = {b}, b_star = {b_star}")
```

```
b = [2 1], b_{star} = [2. 1.]
```

### Column Space and Rank

- The column space of a matrix represents all possible linear combinations of its columns.
- It forms a basis for the space of solutions when solving systems of linear equations represented by the matrix
- The rank of a matrix is the dimension of its column space

```
1 A = np.array([[0, 2], [3, 4]])
2 matrix_rank(A)
```

2

Hence, can solve Ax=b for any  $b\in\mathbb{R}^2$  since the column space is the entire space  $\mathbb{R}^2$ 

# Singular Matrices

On the other hand, note

1

So we can only solve 
$$Ax=b$$
 for  $b \propto egin{bmatrix} 1 \\ 2 \end{bmatrix} \propto egin{bmatrix} 2 \\ 4 \end{bmatrix}$ 

# **Checking Singularity**

```
A = np.array([[1, 2], [2, 4]])
   # An (expensive) way to check if A is singular is if det(A) = 0
   print(det(A) == 0.0)
   print(matrix rank(A) != A.shape[0]) # or check rank
   # Check before inverting or use exceptions
   try:
       inv(A)
       print("Matrix is not singular (invertible).")
8
   except np.linalg.LinAlgError:
9
       print("Matrix is singular (non-invertible).")
10
```

True

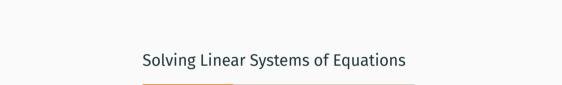

True

Matrix is singular (non-invertible).

#### Determinant is Not Scale Invariant

- · Reminder: numerical precision in calculations makes it hard to compare to zero
- The determinate is useful but depends on the scale of the matrix
- · A more robust alternative is the condition number (more next lecture)

```
eps, K = 1e-8, 100000
A = np.arrav([[1, 2], [1 + eps, 2 + eps]])
print(f"det(A)=\{det(A):.5g\}, det(K*A)=\{det(K*A):.5g\}")
print(f"cond(A)=\{cond(A):.5g\}, cond(K*A)=\{cond(A):.5g\},")
print(f"det(inv(A))=\{det(inv(A)):.5g\}, cond(inv(A))=\{cond(inv(A)):.5g\}"\}
det(A) = -1e - 08. det(K*A) = -100
cond(A)=1e+09, cond(K*A)=1e+09,
det(inv(A)) = -1e + 08, cond(inv(A)) = 1e + 09
```

## Solving Systems with Multiple RHS

- · Inverse is nice because you can reuse the  $A^{-1}$  to solve Ax=b for many b
- · However, you can do this with **solve** as well
- Or can reuse LR factorizations (discussed next)

```
A = np.array([[0, 2], [3, 4]])
B = np.array([[2,3], [1,2]]) # [2,1] and [3,2] as columns
# or: B = np.column stack([np.array([2, 1]),np.array([3,2])])
X = solve(A, B) \# Solve AX = B for X
print(X)
print(f"Checking: A*{X[:,0]} = {A@X[:,0]} = {B[:,0]}, column of B")
[[-1.
             -1.333333333
 1.
             1.5
Checking: A*[-1. 1.] = [2. 1.] = [2 1], column of B
```

# LU(P) Decompositions

- · We can "factor" any square A into PA=LU for triangular L and U. Invertible can have A=LU, called the LU decomposition. "P" is for partial-pivoting
- $\cdot$  Singular matrices may not have full-rank L or U matrices

```
A = np.array([[1, 2], [2, 4]])
P, L, U = lu(A)
print(f"L*U =\n{L @ U}")
print(f"P*A =\n{P @ A}")
```

```
L*U =
[[2. 4.]
[1. 2.]]
P*A =
[[2. 4.]
[1. 2.]]
```

### P, U, and L

The  ${\cal P}$  matrix is a permutation matrix of "pivots" the others are triangular

```
print(f"P = n{P}")
print(f"L = \n\{L\}")
print(f"U =\n{U}")
P =
[[0. 1.]
 [1. 0.]]
I =
[[1. 0.]
 [0.5 1.]
U =
[[2. 4.]
 [0. 0.]]
```

### LU Decompositions and Systems of Equations

- · Pivoting is typically implied when talking about "LU"
- Used in the default solve algorithm (without more structure)
- $\cdot$  Solving systems of equations with triangular matrices: for Ax=LUx=b
  - 1. Define y = Ux
  - 2. Solve Ly=b for y and Ux=y for x
- Since both are triangular, process is  ${\cal O}(N^2)$  (but LU itself  ${\cal O}(N^3)$ )
- Could be used to find inv
  - $\cdot A = LU$  then  $AA^{-1} = I = LUA^{-1} = I$
  - · Solve for Y in LY=I, then solve  $UA^{-1}=Y$
- Tight connection to textbook Gaussian elimination (including pivoting)

# LU for Non-Singular Matrices

```
A = np.array([[1, 2], [3, 4]])
P, L, U = lu(A)
print(f"L*U = \n\{L \otimes U\}")
print(f"P*A = \n{P @ A}")
L*U =
[[3. 4.]
 [1. 2.]]
P*A =
[[3. 4.]
 [1. 2.]]
```

# L, U, P

```
print(f"P = \n{P}")
print(f"L =\n{L}")
print(f"U = n\{U\}")
[[0. 1.]
 [1. 0.]]
L =
[[1.
              0.
 [0.33333333 1.
U =
[[3.
              4.
 [0.
              0.66666667]]
```

## **Backwards Substitution Example**

$$Ux = b$$

$$U \equiv \begin{bmatrix} 3 & 1 \\ 0 & 2 \end{bmatrix}, \quad b = \begin{bmatrix} 7 \\ 2 \end{bmatrix}$$

Solving bottom row for  $x_2$ 

$$2x_2 = 2, \quad x_2 = 1$$

Move up a row, solving for  $x_1$ , substituting for  $x_2$ 

$$3x_1 + 1x_2 = 7$$
,  $3x_1 + 1 \times 1 = 7$ ,  $x_1 = 2$ 

Generalizes to many rows. For L it is "forward substitution"

## Use Triangular Structure if Possible

- $\cdot$  Triangular matrices of size N can be solved with back substitution in  $O(N^2)$
- Is  ${\cal O}(N^2)$  good or bad? Beats,  ${\cal O}(N^3)$  typical of general methods

## Symmetric Matrix Structure

Another common matrix type are symmetric,  $A=A^T$ 

```
A = np.array([[1, 2], [2, 5]]) # also posdef, not singular
b = np.array([1,4])
print(f"Symmetric A? {scipy.linalg.issymmetric(A)}")
solve(A, b, assume_a="sym") # could also use "pos" since positive definite
Symmetric A? True
array([-3., 2.])
```

#### **Positive Definite Matrices**

- · A symmetric matrix A is positive definite if  $x^TAx>0$  for all  $x\neq 0$
- · Useful in many areas, such as covariance matrices. Example

```
1  A = np.array([[1, 2], [2, 5]])
2  x = np.array([0, 1]) # can't really check for all x
3  print(f"x^T A x = {x.T @ A @ x}")
```

$$x^T A x = 5$$

· Example of a symmetric matrix that is not positive definite

```
1 A = np.array([[1, 2], [2, 0]])
2 print(f"x^T A x = {x.T @ A @ x}") # one counterexample is enough
```

$$x^T A x = 0$$

• We can check these with eigenvalues

## **Cholesky Decomposition**

L\*L^T = [[1. 2.] [2. 5.]]

- · For symmetric positive definite matrices:  $L=U^{T}$
- Called a Cholesky decomposition:  $A = LL^T$  for a lower triangular matrix L.
- $\cdot$  Equivalently, could find A =  $U^T U$  for an upper triangular matrix U

```
1 A = np.array([[1, 2], [2, 5]])
2 L = cholesky(A, lower=True) # cholesky also defined for upper=True
3 print(L)
4 print(f"L*L^T =\n{L @ L.T}")

[[1. 0.]
[2. 1.]]
```

25

## Solving Positive Definite Systems

[-3. 2.] [-3. 2.]

```
A = np.array([[1, 2], [2, 5]])
  b = np.arrav([1.4])
  print(solve(A, b, assume a="pos")) # uses cholesky internally
4
  L = cholesky(A, lower=True)
  v = solve triangular(L. b. lower=True)
  x = solve_triangular(L.T, y, lower=False)
  print(x)
```

## Cholesky for Covariance Matrices

- · Covariance matrices are positive-definite, semi-definite if degenerate
- Key property of Gaussian random variables:

$$\cdot \ \, X \sim N(\mu, \Sigma) \mbox{ for } \mu \in \mathbb{R}^N, \Sigma \in \mathbb{R}^{N \times N}$$

$$\cdot \ \, X = \mu + AZ \mbox{ for } Z \sim N(0_N, I_N) \mbox{ where } AA^T = \Sigma$$

 $\boldsymbol{\cdot}$  That is, A is the Cholesky decomposition of the covariance matrix

Eigenvalues and Eigenvectors

# Eigenvalues and Eigenvectors

 $\cdot$  For a square A, an eigenvector x and eigenvalue  $\lambda$  satisfy

$$Ax = \lambda x$$

- $\cdot$   $A \in \mathbb{R}^{N imes N}$  has N eigenvalue/eigenvector pairs, possible multiplicity of  $\lambda$
- · Intuition: x is a direction  $Ax \propto x$  and  $\lambda$  says how much it "stretches"
- Properties:
  - For any eigenvector x and scalar c then  $cx \propto Ax$  as well
  - · Symmetric matrices have real eigenvalues and orthogonal eigenvectors. i.e.  $x_1\cdot x_2=0$  for  $x_1\neq x_2$  eigenvectors. Complex in general
  - · Singular if and only if it has an eigenvalue of zero
  - · Positive (semi)definite if and only if all eigenvalues are strictly (weakly) positive
  - · Diagonal matrix has eigenvalues as its diagonal
  - · Triangular matrix has eigenvalues as its diagonal

## Positive Definite and Eigenvalues

You cannot check  $x^TAx>0$  for all x. Check if "stretching" is positive

```
A = np.array([[3, 1], [2, 1]])
# A eigs = np.real(eigvals(A)) # symmetric matrices have real eigenvalues
A eigs = eigvalsh(A) # specialized for symmetric/hermitian matrices
print(A eigs)
is positive definite = np.all(A eigs > 0)
is_positive_semi_definite = np.all(A_eigs >= 0) # or eigvals(A) >= -eps
print(f"pos-def? {is positive definite}")
print(f"pos-semi-def? {is positive semi definite}")
```

```
[-0.23606798 4.23606798]
pos-def? False
pos-semi-def? False
```

### Positive Semi-Definite Matrices May Have a Zero Eigenvalue

The simplest positive-semi-definite (but not posdef) matrix is

```
A_eigs = eigvalsh(np.array([[1, 0], [0, 0]]))
print(A eigs)
is positive definite = np.all(A eigs > 0)
is positive semi definite = np.all(A eigs >= 0) # or eigvals(A) >= -eps
print(f"pos-def? {is positive definite}")
print(f"pos-semi-def? {is_positive semi definite}")
[0, 1,]
pos-def? False
pos-semi-def? True
```

# **Eigenvalue Decomposition**

 $\cdot$  For square, symmetric, non-singular matrix A factor into

$$A = Q\Lambda Q^{-1}$$

- $\cdot \ Q$  is a matrix of eigenvectors,  $\Lambda$  is a diagonal matrix of eigenvalues (in order)
- $\cdot$  For symmetric matrices, the eigenvectors are orthogonal and  $Q^{-1}Q=Q^TQ=I$ , and we can think of them as forming an orthonormal basis
- · Orthogonal matrices can be thought of as rotations without stretching
- · More general matrices all have a Singular Value Decomposition (SVD)
- With symmetric A, an interpretation of Ax is that we can first rotate x into the Q basis, then stretch by  $\Lambda$ , then rotate back
- $\cdot$  Can be used to find  $A^t$  for large t (e.g. for Markov chains)
  - $\cdot P^t$ , i.e.  $P \cdot P \cdot \dots \cdot P$  for t times
  - $\cdot \ P = Q \Lambda Q^{-1}$  then  $P^t = Q \Lambda^t Q^{-1}$  where  $\Lambda^t$  is just the pointwise power

# Eigenvalue Decomposition of Symmetric Matrix Example

```
A = np.array([[2, 1], [1, 3]])
   Lambda. 0 = eig(A)
2
   print(f"eigenvectors are column-by-column in Q = \ln\{Q\}")
   print(f"eigenvalues are in Lambda = {Lambda}")
  print(f"Q Lambda Q^T =\n{Q @ np.diag(np.real(Lambda)) @ Q.T}")
   eigenvectors are column-by-column in Q =
   [[-0.85065081 -0.52573111]
    [ 0.52573111 -0.85065081]]
   eigenvalues are in Lambda = [1.38196601+0.i 3.61803399+0.i]
  O Lambda O^T =
   \lceil \lceil 2. 1. \rceil
    [1. 3.]]
```

## Spectral Radius is Maximum Absolute Eigenvalue

- · If any  $\lambda \in \Lambda$  are >1 can see this would explode
- Useful for seeing if iteration  $\boldsymbol{x}_{t+1} = A\boldsymbol{x}_t$  from a  $\boldsymbol{x}_0$  explodes

#### Definition (Spectral Radius)

The spectral radius of matrix A is  $\rho(A) = \max_{\lambda \in \Lambda} |\lambda|$ 

Least Squares and the Normal

**Equations** 

### **Least Squares**

Given a matrix  $X \in \mathbb{R}^{N \times M}$  and a vector  $y \in \mathbb{R}^N$ , we want to find  $\beta \in \mathbb{R}^M$  such that

$$\min_{\beta} ||y - X\beta||^2$$
, that is,

$$\min_{\beta} \sum_{n=1}^N \frac{1}{N} (y_n - X_n \cdot \beta)^2$$

Where  $\boldsymbol{X}_n$  is n'th row. Take FOCS and rearrange to get

$$(X^TX)\beta = X^Ty$$

## Solving the Normal Equations

- $\cdot$  The X is often referred to as the "design matrix".  $X^TX$  as the Gram matrix
- · Can form  $A=X^TX$  and  $b=X^Ty$  and solve  $A\beta=b$ .
  - Or invert  $X^TX$  to get  $\beta = (X^TX)^{-1}X^Ty$
  - · Note that  $X^TX$  is symmetric and, if X is full-rank, positive definite
- In practice, use the lstsq function in scipy
  - It uses better algorithms using eigenvectors. More stable (see next lecture on conditioning)
  - · One algorithm uses another factoring, the QR decomposition
  - $\cdot$  There, X=QR for Q orthogonal and R upper triangular. See QR Decomposition for more
- · We are exploring linear algebra in this lecture
  - For applied work use higher-level libraries like statsmodels (integrated well with pandas and seaborn)
  - See statsmodels docs for R-style notation
  - See QuanteEcon OLS for later

## **Example of LLS using Scipy**

```
N. M = 100.5
X = np.random.randn(N. M)
beta = np.random.randn(M)
y = X \otimes beta + 0.05 * np.random.randn(N)
beta hat, residuals, rank, s = scipy.linalg.lstsq(X, y)
print(f"beta =\n {beta}\nbeta hat =\n{beta hat}")
beta =
 0.5356111 0.00589317 -0.69347853 -1.32956515 -0.95302447
beta hat =
[ 0.54533529  0.00168887 -0.69943815 -1.33164324 -0.95063408]
```

## Solving using the Normal Equations

Or we can solve it directly. Provide matrix structure (so it can use a Cholesky)

```
beta_hat = solve(X.T @ X, X.T @ y, assume_a="pos")
print(f"beta =\n {beta}\nbeta_hat =\n{beta_hat}")

beta =
   [ 0.5356111     0.00589317 -0.69347853 -1.32956515 -0.95302447]
beta_hat =
   [ 0.54533529     0.00168887 -0.69943815 -1.33164324 -0.95063408]
```

## Collinearity in "Tall" Matrices

- $\cdot$  Tall  $\mathbb{R}^{N \times M}$  "design matrices" have N > M and are "overdetermined"
- The rank of a matrix is full rank if all columns are linearly independent
- $\cdot$  You can only identify M parameters with M linearly independent columns

```
1  X = np.array([[1, 2], [2, 5], [3, 7]]) # 3 observations, 2 variables
2  X_col = np.array([[1, 2], [2, 4], [3, 6]]) # all proportional
3  print(f"rank(X) = {matrix_rank(X)}, rank(X_col) = {matrix_rank(X_col)}")

rank(X) = 2, rank(X_col) = 1
```

#### **Collinearity and Estimation**

· If X is not full rank, then  $X^TX$  is not invertible. For example:

- Note that when you start doing operations on matrices, numerical error creeps in, so you
  will not get an exact number
- $\cdot$  The rule-of-thumb with condition numbers is that if it is  $1 \times 10^k$  then you lose about k digits of precision. So this effectively means it is singular
- $\cdot$  Given the singular matrix, this means a continuum of eta will solve the problem

## **lstsq** Solves it? Careful on Interpretation!

- · Since  $X_{col}^T X_{col}$  is singular, we cannot use  ${\tt solve(X.T@X, y)}$
- But what about lstsq methods?
- · As you will see, this gives an answer. Interpretation is hard
- The key is that in the case of non-full rank, you cannot identify individual parameters
  - · Related to "Identification" in econometrics
  - · Having low residuals is not enough

```
y = np.array([5.0, 10.1, 14.9])
beta_hat, residuals, rank, s = scipy.linalg.lstsq(X_col, y)
print(f"beta_hat_col = {beta_hat}")
print(f"rank={rank}, cols={X.shape[1]}, norm(X*beta hat col-y)={norm(residual)}
```

```
beta_hat_col = [0.99857143 1.99714286]
rank=1, cols=2, norm(X*beta_hat_col-y)=0.0
```

## Fat Design Matrices

- Fat  $\mathbb{R}^{N \times M}$  "design matrices" have N < M and are "underdetermined"
- · Less common in econometrics, but useful to understand the structure
- · A continuum  $\beta \in \mathbb{R}^{M-{\rm rank}(X)}$  solve this problem

```
1  X = np.array([[1, 2, 3], [0, 5, 7]]) # 2 rows, 3 variables
2  y = np.array([5, 10])
3  beta_hat, residuals, rank, s = scipy.linalg.lstsq(X, y)
4  print(f"beta_hat = {beta_hat}, rank={rank}, ? residuals = {residuals}")
5  beta_hat = [0.8 0.6 1. ], rank=2, ? residuals = []
```

#### Which Solution?

- Residuals are zero here because there are enough parameters to fit perfectly (i.e., it is underdetermined)
- · Given the multiple solutions, the lstsq is giving

$$\min_{\beta} ||\beta||_2^2$$
 s.t.  $X\beta = y$ 

- · i.e., the "smallest" coefficients which interpolate the data exactly
- · Which trivially fulfills the OLS objective:  $\min_{\beta} ||y X\beta||_2^2$
- · Useful and common in ML, but be very careful when interpreting for economics
  - Tight connections to Bayesian versions of statistical tests
  - But until you understand econometrics and "identification" well, stick to full-rank matrices
  - Advanced topics: search for "Regularization", "Ridgeless Regression" and "Benign Overfitting in Linear Regression."
